Mitigation Modelling of the Leeuwin Class Hydrographic Sonars in Shoalwater Bay

Paul Clarke

Maritime Operations Division
Defence Science and Technology Organisation

DSTO-TR-2121

ABSTRACT

Shoalwater Bay is an important training area for the Royal Australian Navy. To conduct operations in Shoalwater Bay in an environmentally sensitive manner Navy use mitigation strategies during any training exercises. One such mitigation strategy is to have established stand-off ranges, and to cease operations when a marine mammal is within these ranges. This document describes an improved determination of these stand-off ranges based on the effect of acoustic energy emanating from the Leeuwin class hydrographic ship sonars. Modelling methods used and the mitigation ranges calculated are shown.

RELEASE LIMITATION

Approved for public release
Mitigation Modelling of the Leeuwin Class Hydrographic Sonars in Shoalwater Bay

Executive Summary

The ability to conduct training exercises in Shoalwater Bay is an important requirement for the Royal Australian Navy, but Shoalwater Bay is also part of the highly significant Great Barrier Reef Marine Park. To enable the Navy to conduct exercises in Shoalwater Bay in an environmentally sensitive manner, a number of mitigation strategies have been implemented. One strategy in relation to sonars on Leeuwin class hydrographic vessels is to use a stand-off range and to cease sonar transmissions when a marine mammal is within this mitigation range. The RAN Environment Manager requested DSTO to conduct acoustic modelling of the Leeuwin class hydrographic ship sonars in the Shoalwater Bay region to confirm suitable mitigation ranges. This document shows the results from the acoustic modelling.

The Leeuwin class hydrographic ships have a number of different sonars designed for specific operations. The welfare of dolphins and dugongs is the main concern in Shoalwater Bay in reference to hydrographic sonar frequencies. Modelling therefore considered all sonars capable of radiating signals within the auditory frequency range of dolphins, 1 to 150 kHz, and dugongs, 1 to 8 kHz. Sonar operations at frequencies above 200 kHz were not considered since the effects on dolphins and dugongs were assumed inconsequential. The sonar with the lowest operating frequency of 12 kHz (Atlas DESO 25 single beam echo sounder) emits signals above what is believed to be the dugong auditory range, but for the present purposes of arriving at conservative mitigation range estimates, the dugong auditory range was assumed to extend to this frequency.

The acoustic modelling was done using a gaussian beam model called SCAT-RD. This modelling included a number of different environments typical of the Shoalwater Bay region throughout the year. Seafloor roughness and seagrasses were ignored during the modelling, as these would have reduced the sound levels propagated. All modelling was then carried out on a worse-case basis.

This modelling showed that the required mitigation range was dependent on season, sea state, and location, but these dependencies were specific to sonar type and frequency for each sonar. To avoid overly complicating the mitigation strategies, a single worse-case range was recommended for each type of sonar on the Leeuwin class hydrographic ships in respect to each of dolphins and dugongs.
In the case of the Leeuwin class hydrographic ships operating in the vicinity of dolphins, recommended mitigation ranges are as follows:

1. 2000 yards for the CMAS forward looking sonar.
2. 700 yards for the Fansweep 20 Multibeam Echo Sounder and Klein 2000 Towed Light Weight Side Scan Sonar.

In the case of the Leeuwin class hydrographic ships operating in the vicinity of dugongs, the recommended mitigation range is as follows:

4. 200 yards for the Atlas DESO 25 Single Beam Echo Sounder when operating at 12 kHz
Paul Clarke
Maritime Operations Division

Paul Clarke is an Underwater Acoustician within the Maritime Operations Division at DSTO. He joined DSTO in 1995, after completing a Bachelor of Science degree in Oceanography and Meteorology at Flinders University and a Bachelor of Engineering Degree in Mechanical Engineering at the University of South Australia. At DSTO, Paul has worked in many areas underwater acoustics, including work on ambient noise, modelling explosive source levels, acoustic propagation, various inversion techniques to obtain sediment properties, environmental mitigation, and target strength.

1. Introduction

DSTO was requested by the RAN Environment Manager to perform acoustic modelling of the Leeuwin class hydrographic ship sonars in the area of Shoalwater Bay. The work was performed under NAV 05/043, "Impact of environment on operations".

Shoalwater Bay is an important exercise area for the Navy, but it is also part of the world heritage Great Barrier Reef Marine Park [Lee Long 1997]. The bay contains a significant population of the endangered dugong species [Slater 1996]. The dugong (Dugong dugon) population was estimated at around 400 in March 1994 [Marsh 1995]. The auditory range of dugong is estimated at 1 to 8 kHz [URS 2003], so they are at low risk with reference to hydrographic sonar emissions. The Atlas DESO 25 single beam echo sounder however has a low frequency setting at 12 kHz and this was considered in the modelling reported in this document.

The Shoalwater Bay region also contains a number of dolphin species, including bottlenose dolphins (Tursiops truncatus), Indo-Pacific humpback dolphins (Sousa chinensis), and the Irrawaddy dolphins (Orcaella brevirostris) [Marsh 1997]. These dolphins have a hearing sensitivity in the frequency range 1 to 150 kHz [Au 2000]. The received acoustic levels from the Leeuwin class hydrographic ships operating near this frequency range were modelled over various environmental conditions.

The acoustic modelling was done using a gaussian beam ray model, SCAT-RD, to show the expected maximum ranges receiving a sound pressure level over 182 dB and 160 dB throughout Shoalwater Bay. These sound pressure levels of 160 dB and 182 dB were used since they are currently recognised throughout Australia as the threshold for noise disturbance and the threshold for harassment [Polglaze 2003], respectfully.

---

1 SCAT-RD is an in-house front end graphical interface for a gaussian beam model. Enabling a number of transmission loss runs to be automated, thus reducing operator work load.
2. Location

Shoalwater Bay is situated in Queensland, Australia, 22° 15' S 149° 45'E. It is a shallow bay containing a number of sand banks and channels. On the seaward side of the bay there are a variety of channels, bay, inlets, and rocky headlands along the coast [Scott 2006]. The SCATRD modelling uses climatological databases for sound speed as a function of depth and bathymetry. Other parameters including time of year and wind speed were varied over expected ranges to show how these affected the mitigation ranges required.

2.1 Bathymetry

Most of the bay and entrance has a water depth less than 20 m, with only a few deeper sections around the bay entrance (see figure 1). The bathymetry was obtained using a one minute\(^2\) AGSO database [AGSO 2005].

---

\(^2\) One minute is equivalent to 1 nautical mile in the north south direction.
2.2 Sediment

In the bay there are ridges of fine to medium sand. Sediments in the channels between the ridges contain a greater proportion of mud. Offshore the sediments are sandy grading to muddy sands in deeper water [Scott 2006]. The sediment varies from terrigenous sand in the bay to carbonate sand near the entrance, see figure 2.

![Bottom sediments in Shoalwater Bay. (Maxwell 1970)](image)

Shoalwater Bay contains a few seagrass beds, figure 3. Acoustic modelling of seagrass beds at hydrographic frequencies can be difficult due to the high scattering from seagrass at these frequencies. This scattering would normally reduce the coherent signal produced from hydrographic sonars, thus reducing the required mitigation range. Since the purpose of this study is to establish a worst-case mitigation range, the effects of scattering from sea grass was not included in the acoustic modelling.
2.3 Sound Speed Profiles

The sound speed in the ocean is a function of the temperature, salinity, and pressure [Urick 1983]. Since temperature and salinity change with time of year and location around the bay, the sound speed profiles in the Shoalwater Bay region will also vary. The spatial variation was modelled using sound speed profiles taken from the world ocean atlas (WOA) 15 min grid. Four different months during the year were modelled (see figures 4 to 7).
Figure 4: Sound speed profile for January in the Shoalwater Bay region

Figure 5: Sound speed profile for April in the Shoalwater Bay region
Figure 6: Sound speed profile for July in the Shoalwater Bay region

Figure 7: Sound speed profile for October in the Shoalwater Bay region
3. Hydrographic Sonar Parameters used for modelling

There are a number of different sonars used on the Leeuwin class hydrographic ships with different source levels, pulse lengths, frequencies, and beam patterns. The different sonars are listed in table 1 and 2. These parameters are not all the available operating options, but were chosen as they give rise to the highest received sound levels.

3 The source levels in this table are for a reference range of 1 m, i.e. the acoustic sound pressure level received at 1 m from the centre of the transmitter.
The beam pattern and sonar combinations in Table 2 are complex, so some are explained in more detail below:

- The fansweep sonar has a number of beams used to survey the seafloor. Each beam is 3.3° x 1.3°, but all beams combine to give a 161° wide beam underneath the ship (see figure 8).
- The Klein 2000 towed light weight side scan sonar has two broadside beams, one either side of the tow body.
- The EDO Model 3060 doppler velocity log uses 4 beams in different directions underneath the ship. Each beam is 3.5° wide and transmits at an angle of 150° from the ship.
- In the vertical beamwidth column, "down" refers to a signal which is transmitted vertically down towards the seafloor, making a circle or ellipse on the seafloor.

Figure 8: Fansweep multibeam echo sounder, showing the single and combined beams
Figure 9: Beamwidth angles used in tables 2 and 3. For the case shown, horizontal beamwidth is 90°, vertical beamwidth is 15°, and vertical angle is 140°. Vertical beamwidth could also be described as 140° to 155°.

Table 3 shows the parameters used in the acoustic modelling. Pulse lengths were varied from the original parameters, tables 1 and 2, due to limitations in the SCAT-RD acoustic model. Some beamwidths were also increased to compensate for pitch and roll of the ship or tow body. Any variations were chosen so as to increase the mitigation range and present a worst-case. Signals at frequencies above 200 kHz were not considered. Also, the EDO Model 3060 doppler velocity log was only modelled using hand calculations.

4. SCAT-RD Modelling Parameters

Transmission loss calculations were carried out by repeating them at sites on a one minute grid over the bay. At each grid point the TL calculation was done in four directions (north, south, east, and west) to account for spatially dependent depth properties. The modelling used a number of acoustic sub-models, described below, to determine the acoustic attenuation caused by the surface, seafloor, and water volume.

4.1 Surface Attenuation

The surface reflection is very dependent on the surface roughness at hydrographic sonar frequencies. The model used in SCAT-RD to describe the surface attenuation per reflection at different wind speeds was created by the Applied Physics Laboratory, University of Washington [Applied Physics Laboratory 1994]. The surface attenuation curves used in SCAT-RD are shown in figures 10 to 14.

The surface attenuation model uses wind speed as the input to calculate the surface loss, but since Shoalwater Bay is a sheltered environment wind speed is not a good variable to estimate surface roughness\(^4\). Instead this document uses sea state, which correlates well to surface roughness and surface attenuation in a sheltered environment.

![Surface Attenuation vs Grazing Angle for 12 kHz](image)

Figure 10: Surface Attenuation vs Grazing Angle for 12 kHz

\(^4\)The correlation between wind speed and surface roughness in SCAT-RD assumes a fully developed sea (i.e. the sea will not get any rougher at the current wind speed). To obtain a fully developed sea the wind speed must be constant for a minimum time and flow over a large area of sea surface, called fetch.
Figure 11: Surface Attenuation vs Grazing Angle for 33 kHz

Figure 12: Surface Attenuation vs Grazing Angle for 36 kHz
Figure 13: Surface Attenuation vs Grazing Angle for 39 kHz

Figure 14: Surface Attenuation vs Grazing Angle for 100 kHz
4.2 Seafloor Attenuation

The seafloor in the Shoalwater Bay region varied from muddy sand to medium sand [Scott 2006] in the regions of interest. The seafloor was modelled using the parameters for the most reflective sediment, thus giving the longest mitigation ranges. SCAT-RD used the Rayleigh specular reflection model to determine the seafloor attenuation [C. B. Officer 1958]. This model does not include any reflection scattering losses so represents an over prediction of received level. The attenuation curves used in SCAT-RD are shown in figure 15.

As a comparison the MGS model [Yarger 1976] has also been plotted in figure 15. This plot shows that for high grazing angles (short ranges) the MGS model should give a lower TL and produce a slightly higher mitigation range. For ranges over 65 m the grazing angle is less and the MGS model should give a higher TL than the Rayleigh model, which would result in shorter mitigation ranges for MGS. Since the expected mitigation ranges are over 500 m SCAT-RD used the Rayleigh model, giving a worst-case result.

![Seafloor Attenuation vs grazing angle for Shoalwater Bay. This is frequency independent at hydrographic frequencies for the Rayleigh and MGS models.](image)

4.3 Volume Attenuation

SCAT-RD used the Francois – Garrison model to determine the attenuation of sound due to seawater absorption [Francois – Garrison 1982].
5. Mitigation Range Calculation

The modelling of the acoustic signal radiated by the hydrographic sonars was done for a number of different environmental conditions including:

- Sea states 0, 1, 2, and 4.
- Typical sound speed profiles for January, April, July, and October.
- Sonar orientations north, south, east, and west.
- Water depths according to location throughout the Shoalwater Bay region.

The most reflective sediment type within the bay (medium sand) was used for all the modelling, producing a worst-case transmission loss. This was done to remove any uncertainty about sediment variations throughout the bay affecting the modelling results.

The mitigation ranges were obtained according to a worst-case selection process to reduce the amount of modelling data to a usable form, as follows:

1. SCAT-RD transmission loss (TL) modelling was performed for each combination of the different environmental conditions with, in turn, the sonar centred at each point over the 1 minute grid encompassing Shoalwater Bay (see figure 16).
2. Each output from SCAT-RD contained TL vs range and depth. These output data were reduced by finding the worst-case (minimum) TL over the depths 0 to 150m for each range step, thus producing TL vs range for the different environmental conditions for each point at which the sonar was located.
3. The TL vs range results for the four directions at each location were compared using the worst-case selection criteria, reducing the data to one set of TL vs range at each location, sea state, and season.
4. This TL data was then used to determine the maximum (worst-case) received acoustic pressure level around the sonar while transmitting using the formula below:

   \[ IL = SL - TL \]  

   (equation 1)

   where \( IL \) = received (incident) acoustic pressure level
   \( SL \) = source level of the hydrographic sonar
   \( TL \) = worst-case transmission loss

   This gave the IL vs range at each location, sea state, and season.
5. Next the worst-case ranges at each location were found for received acoustic pressure levels of 160 dB and 182 dB. This produced plots of mitigation ranges required for each sea state and season, see appendix A. Since only worst-case TL was used during the previous steps, with no averaging, these plots show the maximum required ranges for different locations, sea states, and seasons to experience incident levels less than 160 or 182 dB, respectively.
6. The mitigation range plots for different sea states and seasons were then compared using the worst-case criteria to give the maximum mitigation ranges required for any of the environmental conditions around Shoalwater Bay (see Chapter 7).
Figure 16: Mitigation range calculation procedure for one location, sea state, and season
5.1 EDO Model 3060 Doppler Velocity Log

The EDO doppler velocity log had a frequency of 171 kHz, which was above the frequency limit of SCAT-RD. Since 171 kHz was also above the expected 150 kHz hearing threshold limit of dolphins a simplified method was used to get the expected mitigation ranges.

The received acoustic levels were calculated assuming spherical spreading existed and sea water absorption (see table 4). A conservative value of 30 dB/km [Fisher 1977] was used for the sea water absorption.

6. Environmental Dependence

6.1 Seasonal Dependence

The mitigation range plots showed a small to medium dependence on seasonal variations of the environment. These variations were very sound speed dependent. This can be seen in figures 17 to 20, which showed how the required mitigation range changed for different seasons at sea state 0 using the Klein 2000 towed light weight side scan sonar. More plots showing the seasonal variation can be seen in Appendix A.
Figure 17: Mitigation ranges required for a received acoustic pressure level of 160 dB during January at sea state 0 on the Klein 2000 Towed Light Weight Side Scan Sonar over medium sand.

Figure 18: Mitigation ranges required for a received acoustic pressure level of 160 dB during April at sea state 0 on the Klein 2000 Towed Light Weight Side Scan Sonar over medium sand.
Figure 19: Mitigation ranges required for a received acoustic pressure level of 160 dB during July at sea state 0 on the Klein 2000 Towed Light Weight Side Scan Sonar over medium sand.

Figure 20: Mitigation ranges required for a received acoustic pressure level of 160 dB during October at sea state 0 on the Klein 2000 Towed Light Weight Side Scan Sonar over medium sand.
6.2 Sea State Dependence

The mitigation range dependence on sea state was as expected, with the longest mitigation ranges needed for low sea states. The effect of sea surface roughness on attenuating the sound for sea state 0 and 1 was small for all sonars. The change in mitigation range due to increased surface attenuation at sea state 2 and 4 varied depending on the sonars, but always reduced the required mitigation ranges. This effect can be seen in figures 18, 21, 22, and 23. The effect on other sonars can be seen in Appendix A.

Figure 21: Mitigation ranges required for a received acoustic pressure level of 160 dB during April at sea state 1 on the Klein 2000 Towed Light Weight Side Scan Sonar over medium sand

Figure 22: Mitigation ranges required for a received acoustic pressure level of 160 dB during April at sea state 2 on the Klein 2000 Towed Light Weight Side Scan Sonar over medium sand
6.3 Ocean Depth Dependence

All the mitigation range plots for the Leeuwin Class sonars showed significant dependence upon ocean depth (see Appendix A), but due to the varying beam patterns between sonars there were no consistent trends. The CMAS forward looking sonar, fansweep 20 multibeam echo sounder, and Klein 2000 towed light weight side scan sonar all had a reduction in mitigation range with depth, which can be seen in figures 22, 24, 30, and 32. While the Atlas DESO 25 single beam echo sounder increased mitigation range with increasing water depth due to its narrow downward beam pattern.
7. Mitigation Range Results

The mitigation range determination for the different environmental conditions across Shoalwater Bay (see appendix A) have been combined using a worst-case criterion for which the maximum mitigation range is shown. These results are shown in figures 24 to 35. Table 5 shows the maximum determined ranges for each sonar type across all environmental conditions, including location.

Table 5: Maximum mitigation ranges calculated for the Leeuwin class hydrographic sonars

8. Conclusion

Modelling of the received sonar signal levels for the Leeuwin class hydrographic sonars was done for a number of different environmental conditions in and around Shoalwater Bay. The maximum expected mitigation ranges have been determined using different environmental variations including four wind speeds, four different months during the year, and various water depths around the bay.

The modelling results show small to medium seasonal dependence on mitigation ranges resulting from seasonal changes in the sound speed profiles. However sound speed profiles vary significantly over each day and month, so it is not recommended that these monthly averages be used to reduce the mitigation range for one season compared to the other. Ocean water depth had a significant effect on mitigation range, but due to the large variations in beam patterns of the Leeuwin class hydrographic sonars no consistent trend was seen. The CMAS forward looking sonar, fansweep 20 multibeam echo sounder, and Klein 2000 towed light weight side scan sonar all had a reduction in mitigation range with increasing depth, while the Atlas DESO 25 single beam echo sounder had an increase in mitigation range with depth due to its narrow downward beam pattern.

The mitigation range dependence on sea state was as expected, with the longest mitigation ranges needed for low sea states. The effect of sea surface roughness on attenuating the sound for sea state 0 and 1 was small for all sonars. The change in mitigation range due to increased surface attenuation at sea state 2 and 4 varied depending on the sonars, but always reduced the required mitigation ranges. A consistent trend was seen, with the longer the mitigation range at sea state 0 the more effect the higher sea states had on reducing this mitigation range.

The modelling results show a very large difference in the recommended mitigation ranges, depending on which sonar the Leeuwin class hydrographic ship is using. To avoid overly complicating the mitigation strategies, a single worse-case range is recommended for each type of sonar on the Leeuwin class hydrographic ships in respect to each of dolphins and dugongs.

In the case of the Leeuwin class hydrographic ships operating in the vicinity of dolphins, recommended mitigation ranges are as follows:

1. 2000 yards for the CMAS Forward Looking Sonar.
2. 700 yards for the Fansweep 20 Multibeam Echo Sounder and Klein 2000 Towed Light Weight Side Scan Sonar.

In the case of the Leeuwin class hydrographic ships operating in the vicinity of dugongs, the recommended mitigation range is as follows:

4. 200 yards for the Atlas DESO 25 Single Beam Echo Sounder when operating at 12 kHz
9. Acknowledgments

The author wishes to thank the following people for their efforts in producing this document:

- CMDR Fiona Smith, RAN, and Dr Stuart Anstee, DSTO, in obtaining the required Leeuwin class hydrographic sonar parameters used in this report.
- John Polglaze, Principal Environmental Scientist in URS Australia, when comparing the results to current mitigation procedures and advising Navy if any modifications were required to the current procedures.

Mitigation Modelling of the Leeuwin Class Hydrographic Sonars in Shoalwater Bay

Shoalwater Bay is an important training area for the Royal Australian Navy. To conduct operations in Shoalwater Bay in an environmentally sensitive manner Navy use mitigation strategies during any training exercises. One such mitigation strategy is to have established stand-off ranges, and to cease operations when a marine mammal is within these ranges. This document describes an improved determination of these stand-off ranges based on the effect of acoustic energy emanating from the Leeuwin class hydrographic ship sonars. Modelling methods used and the mitigation ranges calculated are shown.
